Abstract

This paper proposes a new mechanism by which country size and international trade affect macroeconomic volatility. We study a multi-country, multi-sector model with heterogeneous firms that are subject to idiosyncratic firm-specific shocks. When the distribution of firm sizes follows a power law with exponent sufficiently close to $-1$, the idiosyncratic shocks to large firms have an impact on aggregate volatility. We explore the quantitative properties of the model calibrated to data for the 50 largest economies in the world. Smaller countries have fewer firms, and thus higher volatility. The model performs well in matching this pattern both qualitatively and quantitatively: the rate at which macroeconomic volatility decreases in country size in the model is very close to what is found in the data. Opening to trade increases the importance of large firms to the economy, thus raising macroeconomic volatility. Our simulation exercise shows that the contribution of trade to aggregate fluctuations depends strongly on country size: in an economy such as the U.S., that accounts for one-third of world GDP, international trade increases volatility by about 3.5%. By contrast, trade increases aggregate volatility by some 15-20% in a small open economy, such as Denmark or Romania.

1 Introduction

Macroeconomic volatility varies substantially across economies. Over the past 35 years, the standard deviation of per capita GDP growth is 2.5 times higher in non-OECD countries compared to the OECD countries. Understanding the sources of these differences is important, as aggregate volatility itself has an impact on a wide variety of economic outcomes.\(^1\)

This paper investigates the role of large firms in explaining cross-country differences in aggregate volatility. We show that the impact of large firms on aggregate volatility can help account for two robust empirical regularities: (i) smaller countries are more volatile; and (ii) more open countries are more volatile.\(^2\) The key ingredient of our study is that the distribution of firm size is very fat-tailed – the typical economy is dominated by a few very large firms (Axtell, 2001). In a recent contribution, Gabaix (2010) demonstrates that under these conditions, idiosyncratic shocks to individual firms do not average out and can instead generate aggregate fluctuations (see also Delli Gatti et al., 2005). The economy is “granular,” rather than smooth. Gabaix (2010) provides both statistical and anecdotal evidence that even in the largest and most diversified economy in the world – the United States – the biggest firms can appreciably affect macroeconomic fluctuations.

We develop a theoretical and quantitative framework to study the consequences of this phenomenon in a large cross-section of countries. The analysis is based on the canonical model of heterogeneous firms in the spirit of Melitz (2003) and Eaton et al. (2008). In order to study the impact of large firms on aggregate fluctuations, we must model both the equilibrium total number of firms and as well as their size distribution. To capture the former, our framework endogenizes the equilibrium mass of potential entrepreneurs through a free entry condition. We then show how the model can be calibrated to match the observed firm size distribution. The quantitative framework has a number of realistic features, such as a non-traded sector and input-output linkages between traded and non-traded sectors calibrated to the observed Input-Output tables. The model is solved using data for the 50 largest economies in the world by total GDP.

Our main results can be summarized as follows. First, the model endogenously generates the negative relationship between country size and aggregate volatility. The reason is that

\(^1\)Numerous studies identify its effects on long-run growth (Ramey and Ramey, 1995), welfare (Pallage and Robe, 2003; Barlevy, 2004), as well as inequality and poverty (Gavin and Hausmann, 1998; Laursen and Mahajan, 2005).

\(^2\)Canning et al. (1998) and Furceri and Karras (2007), among others, find that smaller countries are more volatile. A number of empirical studies show that trade openness is associated with higher volatility in a cross-section of countries (Easterly et al., 2001; Kose et al., 2003), as well as at the industry level (di Giovanni and Levchenko, 2009).
smaller countries will have a smaller equilibrium number of firms (a result known since at least Krugman, 1980), and thus shocks to the largest firms will matter more for aggregate volatility. In effect, smaller economies are less diversified, when diversification is measured at the firm level. The model matches this relationship both qualitatively, but also quantitatively: the rate at which volatility decreases in country size in the model is very similar to what is observed in the data. Both in the model and in the data, a typical country that accounts for 0.5% of world GDP (such as Poland or South Africa) has aggregate volatility that is 2 times higher than the largest economy in the world – the U.S..

Second, when it comes to the impact of international trade on volatility there are two effects, which we label “net entry” and “selection into exporting.” When a country opens to trade, the equilibrium number of potential entrepreneurs increases (Krugman, 1980; Melitz, 2003). All else equal, this net entry effect drives down aggregate volatility when a country opens to trade. At the same time, only the largest and most productive firms export, while smaller firms shrink or disappear. This selection into exporting effect implies that after trade opening the biggest firms become even larger relative to the size of the economy, thus contributing more to the overall GDP fluctuations. Which effect dominates depends on parameter values.

In the first counterfactual exercise, we compute what aggregate volatility would be for each country in autarky, and compare it to the volatility under the current trade regime. It turns out that at the levels of trade openness observed today, international trade increases granular volatility relative to autarky in every country. The importance of trade for aggregate volatility varies greatly depending on country characteristics. In the largest economies like Japan or the U.S., aggregate volatility is only 1.8-3.5% higher than it would have been in complete autarky. In small, but remote economies such as South Africa or New Zealand, trade raises volatility by about 10% compared to autarky. Finally, in small, highly integrated economies such as Denmark or Romania, international trade raises aggregate volatility by some 15-20%.

The result that at the current levels of openness, trade contributes positively to aggregate volatility is in line with existing empirical evidence. However, we also find that the effect is in some cases non-monotonic: further reductions in trade barriers can actually reduce granular volatility slightly in some countries. We compute the change in aggregate volatility that would occur if trade costs decreased below their current levels. Our simulations show that a 50% reduction in international trade costs will on average leave aggregate volatility unchanged in our set of countries, with the impact ranging from a negative 2.7% to a positive
8.4%. Thus, as trade costs fall below their current levels, the net entry effect practically cancels out the selection into exporting effect on average. In addition, the magnitude and sign of the impact depends strongly on country size: when trade costs fall below their current levels, volatility increases the most in the largest countries (the G-8), where the net entry effect is least pronounced. Correspondingly, volatility falls the most in the smaller countries (Israel, Venezuela), which tend to experience larger changes in net entry.

Anecdotal evidence on the importance of large firms for aggregate fluctuations abounds. Here, we describe two examples in which the roles of country size and international trade are especially evident. In New Zealand one firm, Fonterra, is responsible for a full one-third of global dairy exports (it is the world’s single largest exporter of dairy products). Such a large exporter from such a small country would clearly matter for the macroeconomy. Indeed, Fonterra’s sales account for 20% of New Zealand’s overall exports, and 7% of its GDP.\(^3\)

Two additional points about this firm are worth noting. First, 95% of Fonterra’s output is exported. Thus, international trade clearly plays a prominent role in making Fonterra as large as it is. And second, the distribution of firm size in the dairy sector is indeed highly skewed. The second largest producer of dairy products in New Zealand is 1.3% the size of Fonterra.\(^4\) This phenomenon is not confined to commodity exporting countries. In Korea, a larger manufacturing-based economy, the 10 biggest business groups account for 54% of GDP and 51% of total exports. Even among the top 10, the distribution of firm size and total exports is extremely skewed. The largest one, Samsung, is responsible for 23% of exports and 14% of GDP (see Figure 1).\(^5\)

The theoretical link between country size, trade openness, and volatility we explore in this paper has not previously been proposed. Head (1995) and Crucini (1997) examine the relationship between country size and volatility in a 2-country international real business cycle (IRBC) model. In those papers, the smaller country has higher volatility because the world interest rate is less sensitive to shocks occurring in that country. Thus, following a

\(^3\)It is important to note that GDP represents value added, and thus Fonterra’s total sales are less than 7% of the total sales of all firms in New Zealand. However, because exports are recorded as total sales, Fonterra’s export sales are directly comparable to New Zealand’s total exports. The same caveat applies to the example that follows.

\(^5\)It turns out that the size distribution of firms is quite skewed even within business groups. For instance, breaking Samsung down into its constituent firms reveals that the sales of Samsung Electronics alone accounted for 7% of GDP and 15.5% of Korea’s exports in 2006. We would like to thank Wonhyuk Lim of KDI for providing us with data on Korean firm and business group sales and exports.
positive shock it can expand investment without much of an impact on interest rates. Our explanation for the size-volatility relationship is qualitatively different, and relies instead on the notion that smaller countries will have fewer firms. When it comes to the relationship between trade openness and volatility, traditional explanations have focused on the propagation of global demand or supply shocks (Newbery and Stiglitz, 1984), or on the notion that a more open economy is specialized in fewer sectors. Kraay and Ventura (2007) argue that developing countries are more volatile than developed ones because their comparative advantage is in goods with more elastic product demand and factor supply. We show that trade can increase volatility even if the nature of shocks affecting the firms is unchanged upon opening. Our model also reveals that what matters is not only diversification across sectors, but also across firms within the economy. Finally, our mechanism does not rely on cross-country differences in elasticities in goods and factor markets.

This paper is part of a small but growing literature that studies the relationship between the production structure, international trade, and the macroeconomy. In our previous work (di Giovanni and Levchenko, 2009), we use sector-level data to demonstrate that trade openness has a robust positive effect on sector-specific volatility, and that it results in greater sectoral specialization. In di Giovanni and Levchenko (2010b), we argue that countries specializing in especially risky sectors will experience higher macroeconomic volatility than countries exporting in less volatile sectors. While the results in these two papers are informative, the use of sector-level data implies that we cannot be precise about the specific mechanisms at work in the trade-volatility link. Canals et al. (2007) analyze sector-level export data and demonstrate that exports are highly undiversified, both across sectors and across destinations. Furthermore, they show that this feature of export baskets can explain why aggregate macroeconomic variables cannot account for much of the movements in the current account.

6 Appendix A implements the canonical IRBC model of Backus et al. (1995), and examines the relationship between country size and volatility, and between trade openness and volatility, in that model. It turns out that while the calibrated IRBC model can produce higher volatility in smaller countries, the relationship between country size and volatility in that model is two orders of magnitude flatter than what is observed in the data. The relationship between trade openness and volatility in the IRBC model is ambiguous, its sign depending crucially on the elasticity of substitution between domestic and foreign goods.

7 Koren and Tenreyro (2007) explore the importance of sector-specific shocks in explaining the relationship between a country’s level of development and its aggregate volatility.

8 Our work is complementary to the research agenda that studies the impact of firm dynamics on macroeconomic outcomes in 2-country IRBC models. Ghironi and Melitz (2005) use the heterogeneous firms model to help account for the persistence of deviations from purchasing power parity, while Alessandria and Choi (2007) evaluate the quantitative importance of firm entry and exit for aggregate trade dynamics. An important difference between these papers and our work is that these contributions examine consequences of aggregate shocks, while in paper all the shocks are at the firm level. In addition, our work features
The rest of the paper is organized as follows. Section 2 presents the theoretical framework. Section 3 simulates the model economy and presents the main quantitative and empirical results. Section 4 presents robustness checks and results based on model perturbations. Section 5 concludes.

2 Theoretical Framework

Consider a model in the spirit of Melitz (2003), but with a discrete number of goods as in Krugman (1980). The world is comprised of \( C \) countries, indexed by \( i, j = 1, \ldots, C \). In each country there are two broad sectors, the tradeable \( T \) and the non-tradeable \( N \). In country \( i \), consumers maximize

\[
\max_{\{c_i^N, c_i^T\}} \left( \sum_{k=1}^{J_i^N} c_i^N (k) \right)^{\frac{\alpha}{\varepsilon_N-1}} \left( \sum_{k=1}^{J_i^T} c_i^T (k) \right)^{\frac{1-\alpha}{\varepsilon_T-1}}
\]

s.t.

\[
\sum_{k=1}^{J_i^N} p_i^N (k) c_i^N (k) + \sum_{k=1}^{J_i^T} p_i^T (k) c_i^T (k) = Y_i,
\]

where \( c_i^s(k) \) is consumption of good \( k \) belonging to sector \( s = N, T \) in country \( i \), \( p_i^s(k) \) is the price of this good, \( Y_i \) is total final consumption expenditure in the economy, and \( J_i^s \) is the number of varieties consumed in sector \( s \) in country \( i \), coming from all countries. Since consumer preferences are Cobb-Douglas in CES aggregates of \( N \) and \( T \), it is well known that consumption expenditure on sector \( N \) is equal to \( \alpha Y_i \), and on the \( T \) sector, \( (1-\alpha)Y_i \).

The CES composites of both \( N \) and \( T \) are used both as consumption and as intermediate inputs in production. Let \( X_i^s \) denote the total spending – final and intermediate – on sector \( s = N, T \) in country \( i \). Given this total expenditure, it is well known that demand for an individual variety \( k \) is equal to

\[
c_i^s(k) = \frac{X_i^s}{(P_i^s)^{1-\varepsilon_s} p_i^s(k)^{-\varepsilon_s}},
\]

in country \( i \), where \( P_i^s \) is the ideal price index sector \( s \) in this economy,

\[
P_i^s = \left[ \sum_{k=1}^{J_i^s} p_i^s(k)^{1-\varepsilon_s} \right]^{\frac{1}{1-\varepsilon_s}}.
\]

multiple countries, and explains cross-sectional differences in volatility between countries.
There is one factor of production, labor, with country endowments given by $L_i$, $i = 1, \ldots, C$, and wages denoted by $w_i$. Production in both sectors uses both labor and CES composites of $N$ and $T$ as intermediate inputs. In particular, a firm with marginal cost $a$ must use this many input bundles to produce one unit of output. An input bundle in country $i$ and sector $s$ has a cost $c^s_i = w^s_i \left[ (P^N_i)^{\eta_s} (P^T_i)^{1-\eta_s} \right]^{1-\beta_s}$. That is, production in sector $s = N, T$ requires labor, inputs of $N$, and inputs of $T$. The share of labor in value added, $\beta_s$, and the share of non-tradeable inputs in total input usage, $\eta_s$ both vary by sector.

As in Krugman (1980) and Melitz (2003), each country has a potentially infinite number of potential entrepreneurs with zero outside option. In order to become an entrepreneur, an agent must pay an “exploration” cost $f_e$. Upon paying this cost, the entrepreneur $k$ discovers her productivity, indexed by a marginal cost $a(k)$, and develops an ability to produce a unique variety of $N$ or $T$ valued by consumers and other firms. Thus, each potential firm has some market power: it faces the downward-sloping demand for its variety given by (1).

There are both fixed and variable costs of production and trade. The timing in this economy is depicted in Figure 2. At the beginning of the period, each potential entrant $k = 1, \ldots, I^i_s$ in each $s = N, T$ and $i = 1, \ldots, C$ pays the exploration cost $f_e$ and learns its type, which is the marginal cost $a(k)$. On the basis of this cost, each entrepreneur in country $i$ decides whether or not to pay the fixed cost of production $f_{i^i_s}$, and which, if any, export markets to serve. In the $N$ sector, we assume that trade costs are infinite, and thus a firm in country $i$ may only serve its own market. In sector $T$, to start exporting from country $j$ to country $i$, a firm must pay the fixed cost $f_{ij}$, and an iceberg per-unit cost of $\tau_{ij} > 1$. We normalize the iceberg cost of domestic sales to one: $\tau_{ii} = 1$. Having paid the fixed costs of entering these markets, the firm learns the realization of transitory shock $z(k)$. We assume that $z(k)$ are i.i.d. across firms. Once all of the uncertainty has been realized, each firm produces with a marginal cost $a(k)z(k)$, markets clear, and consumption takes place.

Note that the assumptions we put on the timing of events, namely that the decision to enter markets takes place before $z(k)$ is realized, implies that the realization of the firm-specific transitory shock does not affect the equilibrium number of firms in each market.

\footnote{That is, the firm in country $j$ must ship $\tau_{ij} > 1$ units to country $i$ in order for one unit of the good to arrive there.}

\footnote{The assumption that $z(k)$ is transitory is not crucial for the basic qualitative results in this paper. We adopt it mainly for analytical convenience.}
This simplification lets us analyze the equilibrium production allocation as an approximation around a case in which the variance of \( z \) is zero. That is, we abstract from the extensive margin of exports, and entry and exit of firms in response to transitory shocks.\(^{11}\) This simplification delivers substantial analytical convenience, while it is unlikely to affect the results. This is because the focus of the paper is on the role of the largest firms in generating aggregate volatility, and the largest firms are inframarginal: their entry decision will not be affected by the realization of the transitory shock. Note also that this timing assumption implies that our analytical approach is akin to the common one of analyzing the response to shocks in deviations from a non-stochastic steady state.

Firm \( k \) from country \( j \) selling to country \( i \) thus faces a demand curve given by (1), and has a marginal cost \( \tau_{ij} c_j^s a(k) z(k) \) of serving this market in sector \( s \). As is well known, profit maximizing price is a constant markup over marginal cost, \( p_{is}^s(k) = \frac{X_{is}^s}{(P_{is}^s)^{1-\varepsilon_s}} \left( \frac{\varepsilon_s}{\varepsilon_s - 1} \tau_{ij} c_j^s a(k) z(k) \right)^{-\varepsilon_s} \), and the total ex-post variable profits are:

\[
\pi_{ij}^{V,s}(a(k)z(k)) = \frac{X_{is}^s}{\varepsilon_s (P_{is}^s)^{1-\varepsilon_s}} \left( \frac{\varepsilon_s}{\varepsilon_s - 1} \tau_{ij} c_j^s a(k) z(k) \right)^{1-\varepsilon_s},
\]

where we assume throughout that the only firms that can sell in sector \( N \) in country \( i \) are those based in that country. Note that these are variable profits of a firm in country \( j \) from selling its good to country \( i \) only. These expressions are valid for each country pair \( i,j \), including domestic sales: \( i=j \).

The production structure of the economy is pinned down by (i) the number of entrepreneurs who pay the exploration cost to find out their type in each country and each sector, \( \bar{I}_i^s \), and (ii) the number of firms from each country that actually enter each market and produce. In particular, there is a cutoff marginal cost \( a_{ij} \), above which firms in country \( j \) do not serve market \( i \). Assuming that the firm maximizes expected profits, the cutoff \( a_{ij} \) is given by the following condition:

\[
E \left[ \pi_{ij}^{V,s}(a(k)z(k)) - c_j^s f_{ij}^s \mid a = a_{ij}^s \right] = 0.
\]

To go forward with the analysis, we make the following two assumptions:

**Assumption 1** The marginal entrepreneur is small enough that it ignores the impact of its own realization of \( z(k) \) on the total expenditure \( X_{is}^s \) and the price level \( P_{is}^s \) in all potential destination markets \( i = 1, \ldots, C \) and sectors \( s = N, T \).

\(^{11}\)The adjustment in the extensive margin in response to shocks has been studied by Ghironi and Melitz (2005) and Alessandria and Choi (2007).
Assumption 2 The marginal entrepreneur treats $X_i^s$ and $P_i^s$ as fixed (non-stochastic).

The first assumption is not controversial, and has been made in the literature since Dixit and Stiglitz (1977) and Krugman (1980). The second assumption allows us to take $X_i$ and $P_i$ outside of the expectation operator. It amounts to assuming that the entrepreneur ignores the volatility of GDP and inflation when deciding to enter a market. Under these two assumptions, plugging in the variable profits (3) and taking the expectation over $z$, the zero cutoff profit condition for serving sector $s$ in market $i$ from country $j$ reduces to:

$$a_{ij} = \frac{\varepsilon_s - 1}{\varepsilon_s} \frac{P_i^s}{\tau_{ij} c_j^s} \left( \frac{X_i^s}{\varepsilon_s c_j f_{ij}^s} \right) \frac{1}{\varepsilon_s - 1} = \frac{\varepsilon_s - 1}{\varepsilon_s} \frac{P_i^s}{\tau_{ij} c_j^s} \left( \frac{X_i^s}{\varepsilon_s c_j f_{ij}^s} \right) \frac{1}{\varepsilon_s - 1},$$

(4)

where the second equality comes from normalizing the transitory shocks $z$ such that $E_z (z^{1-\varepsilon}) = 1$.

The equilibrium number of potential entrepreneurs $\bar{I}_i^s$ is then pinned down by the familiar free entry condition in each sector and each country. Entrepreneurs will enter until the expected profit equals the cost of finding out one’s type:

$$E \left[ \sum_{j=1}^C \left( \pi_{j|i}^{V,s}(a(k)z(k)) - c_i^s f_{ji}^s \right) \right] = c_i^s f_{ie}^s,$$

(5)

for each country and sector, where once again in sector $N$, profits can only be positive for $j = i$.

Closing the model involves finding expressions for $a_{ij}^s$, $P_i^s$, and $w_i$ for all $s = N,T$, $i, j = 1, \ldots, C$. The $N$-sector price level in country $i$ can be expressed as follows:

$$P_i^N = \left[ \sum_{k=1}^{I_N^j} \left( \frac{\varepsilon_N}{\varepsilon_N - 1} c_i^N a(k)z(k) \right)^{1-\varepsilon_N} \right]^{1-\varepsilon_N}.$$
where \( I_{ij}^N \) is the number of varieties actually produced in the \( N \) sector in country \( i \). In the traded sector, the price level is given by:

\[
P_i^T = \left[ \frac{1}{c} \sum_{j=1}^C \sum_{k=1}^K \left( \frac{\varepsilon_T}{\varepsilon_T - 1} \tau_{ij} c_j^T a(k) z(k) \right) 1^{1-\varepsilon_T} \right]^{\frac{1}{1-\varepsilon_T}},
\]

where \( I_{ij}^T \) is the number of varieties exported from country \( j \) to country \( i \). As an approximation, we solve for the equilibrium production allocation and the price levels ignoring firm-specific transitory shocks. Taking the expectations over \( a(k) \) and \( z(k) \), and using the fact that \( E_z(z^{1-\varepsilon}) = 1 \), the price levels become:

\[
P_i^N = \left[ \left( \frac{\varepsilon_N}{\varepsilon_N - 1} \right)^{1-\varepsilon_N} I_i^N \left( c_j^N \right)^{1-\varepsilon_N} E_a(a(k)^{1-\varepsilon_N} | a < a_i^N) \right]^{\frac{1}{1-\varepsilon_N}}. \tag{6}
\]

and

\[
P_i^T = \left[ \left( \frac{\varepsilon_T}{\varepsilon_T - 1} \right)^{1-\varepsilon_T} \sum_{j=1}^C I_j^T \left( \tau_{ij} c_j^T \right)^{1-\varepsilon_T} E_a(a(k)^{1-\varepsilon_T} | a < a_i^T) \right]^{\frac{1}{1-\varepsilon_T}}. \tag{7}
\]

In order to solve the model, we must make a distributional assumption on the \( a \)'s:

**Assumption 3** Firm productivity in sector \( s \), 1/\( a \), follows a Pareto\((b_s, \theta_s)\) distribution, where \( b_s \) is the minimum value labor productivity can take, and \( \theta_s \) regulates dispersion.

It is then straightforward to show that the marginal cost, \( a \), has a distribution function \( G_s(a) = (b_s a)^{\theta_s} \) in sector \( s \). Furthermore, following Helpman et al. (2004), we define \( V_s(y) = \int_0^y a^{1-\varepsilon_s} dG_s(a) = \frac{b_s^{\theta_s} \theta_s}{\theta_s - (\varepsilon_s - 1)} y^{\theta_s - (\varepsilon_s - 1)} \). The expression \( V_s(a_{ij}^s) \) is useful for writing the price levels and expected profits in the economy. This implies that \( E_a(a(k)^{1-\varepsilon_s} | a < a_{ij}^s) = V_s(a_{ij}^s) / G_s(a_{ij}^s) \).

The number of actual entrants into market \( i \) from market \( j \) in the \( T \) sector is \( I_{ij}^T = \bar{I}_j^T G_T(a_{ij}^T) \), while the number of actual entrants in the \( N \) sector in country \( i \) is \( I_i^N = \bar{I}_i^N G_N(a_{ii}^N) \). As a result, the price levels can be written as:

\[
P_i^N = \left[ \left( \frac{\varepsilon}{\varepsilon - 1} c_i^N \right)^{1-\varepsilon} \bar{I}_i^N \frac{b_{ij}^N \theta_N}{\theta_N - (\varepsilon_N - 1)} (a_{ii}^N)^{\theta_N - (\varepsilon_N - 1)} \right]^{\frac{1}{1-\varepsilon_N}},
\]

and

\[
P_i^T = \left[ \sum_{j=1}^C \left( \frac{\varepsilon}{\varepsilon - 1} \tau_{ij} c_j^T \right)^{1-\varepsilon} \bar{I}_j^T \frac{b_j^T \theta_T}{\theta_T - (\varepsilon_T - 1)} (a_{ij}^T)^{\theta_T - (\varepsilon_T - 1)} \right]^{\frac{1}{1-\varepsilon_T}},
\]
which, after plugging in the expressions for $a_{ij}^s$ in (4), become:

$$P_i^N = \frac{1}{b_N} \left[ \frac{\theta_N}{\theta_N - (\varepsilon_N - 1)} \right] - \frac{1}{\theta_N} \frac{\varepsilon_N}{\varepsilon_N - 1} \left( \frac{X_i^N}{\varepsilon_N} \right) - \frac{\theta_N - (\varepsilon_N - 1)}{\theta_N (\varepsilon_N - 1)} \left( \frac{I_i^N}{\varepsilon_N} \right) \left( \frac{1}{c_i^N} \right) \left( \frac{1}{c_i^N} \right) \left( \frac{1}{\varepsilon_N - 1} \right)$$

(8)

and

$$P_i^T = \frac{1}{b_T} \left[ \frac{\theta_T}{\theta_T - (\varepsilon_T - 1)} \right] - \frac{1}{\theta_T} \frac{\varepsilon_T}{\varepsilon_T - 1} \left( \frac{X_i^T}{\varepsilon_T} \right) - \frac{\theta_T - (\varepsilon_T - 1)}{\theta_T (\varepsilon_T - 1)} \left( \sum_{j=1}^C \frac{\tilde{I}_j^T}{\tau_{ij}c_j^T} \right) \left( \frac{1}{\tau_{ij}c_j^T} \right) \left( \frac{1}{\varepsilon_T - 1} \right)$$

(9)

Having expressed $P_i^s$ and $a_{ij}^s$ in terms of $X_i^s$ and $w_i$, for all $i, j = 1, \ldots, C$, it remains to close the model by solving for the $X_i^s$'s and $w_i^s$'s. To do this, we impose balanced trade for each country and the market clearing conditions in each sector and country. Since profits are zero, total final expenditure in country $i$ simply equals labor income: $Y_i = w_i L_i$. Total expenditure $X_i^N$ and $X_i^T$ equals final spending plus expenditure on sector $s$ as intermediate inputs in both sectors:

$$X_i^N = \alpha w_i L_i + (1 - \beta_N) \eta_N X_i^N + (1 - \beta_T) \eta_T X_i^T$$

$$X_i^T = (1 - \alpha) w_i L_i + (1 - \beta_N) (1 - \eta_N) X_i^N + (1 - \beta_T) (1 - \eta_T) X_i^T.$$  

Note that even though the $T$-sector has both imports and exports, the assumption that only $T$-sector goods can be traded amounts to imposing balanced trade within the $T$ sector, and thus the second condition must be satisfied in equilibrium as written. These two conditions imply that total spending in each sector is a constant multiple of labor income $w_i L_i$.

The total sales from country $i$ to country $j$ can be written as:

$$X_{ji}^T = \frac{X_j^T}{(P_j^T)^{1-\varepsilon_T}} \left( \frac{\varepsilon_T}{\varepsilon_T - 1} \right)^{1-\varepsilon_T} \frac{\tilde{I}_i^T}{\theta_T - (\varepsilon_T - 1)} (a_{ij}^T)^{\theta_T - (\varepsilon_T - 1)}.$$  

Using the expression for $a_{ij}^T$ in (4), and $P_j^T$ in (9), the total exports from $i$ to $j$ become:

$$X_{ji}^T = \frac{\tilde{I}_i^T}{\sum_{l=1}^C \tilde{I}_l^T} \left( \frac{1}{\tau_{jl}c_l^T} \right)^{\theta_T} \left( \frac{1}{c_l^T} \right)^{\theta_T - (\varepsilon_T - 1)}.$$  

Using the trade balance conditions, $X_i^T = \sum_{j=1}^C X_{ji}^T$ for each $i = 1, \ldots, C$, as well as the property that total spending $X_i^T$ is a constant multiple of $w_i L_i$ leads to the following system
of equations in $w_i$:

$$w_i L_i = \sum_{j=1}^{C} \bar{I}_i^T \left( \frac{\tau_j w_i^{\beta T} \left( \left( P_{N_i} \right)^{\eta T} \left( P_{T_i} \right)^{1-\eta T} \right)^{1-\beta T}}{w_i^{\beta T} \left( \left( P_{N_i} \right)^{\eta T} \left( P_{T_i} \right)^{1-\eta T} \right)^{1-\beta T}} \right)^{\frac{\theta_{T_i}}{e_T - 1}} \sum_{l=1}^{C} \bar{I}_l^T \left( \frac{1}{\tau_l w_l^{\beta T} \left( \left( P_{N_l} \right)^{\eta T} \left( P_{T_l} \right)^{1-\eta T} \right)^{1-\beta T}} \right)^{\frac{\theta_{T_l}}{e_T - 1}} w_j L_j,$$

$$i = 1, \ldots, C. \text{ There are } C - 1 \text{ independent equations in this system, with wage in one of the countries as the numéraire.}$$

A monopolistically competitive equilibrium is a set of prices \( \{w_i, P_{N_i}, P_{T_i}\}_{i=1}^{C} \), and factor allocations such that (i) consumers maximize utility; (ii) firms maximize profits, and (iii) all goods and factor markets clear. The equilibrium is obtained as a solution to \((C - 1) + 2 \times C + 2 \times C\) equations in $w_i$, $P_{N_i}$, $P_{T_i}$, $\bar{I}_N^i$ and $\bar{I}_T^i$ that satisfies equations (5), (8), (9), and (10) for each $i = 1, \ldots, C$. We will solve these equations numerically in order to carry out the main quantitative exercise in this paper.

### 2.1 Power Law in Firm Size, Granularity, and Aggregate Volatility

This economy is granular, that is, idiosyncratic shocks to firms result in aggregate fluctuations, if the distribution of firm size follows a power law with the exponent sufficiently close to 1 in absolute value. Denote by lower case $x(a(k), z(k))$ the sales of an individual firm $k$. Firm sales $x$ in the economy must conform to:

$$\Pr(x > q) = \delta q^{-\zeta}, \quad (11)$$

where $\zeta$ is close to 1. Gabaix (2010, Proposition 2) shows that when the distribution of firm size follows a power law with exponent $\zeta$, the economy is populated by $N$ firms, and each firm has a standard deviation of sales growth equal to $\sigma$, the volatility of GDP is proportional to $\sigma / N^{1 - 1/\zeta}$ for $2 > \zeta > 1$, and to $\sigma / \log N$ when $\zeta = 1$. In other words, when $\zeta < 2$ and thus the distribution of firm size has infinite variance, the conventional Law of Large Numbers does not apply, and aggregate volatility decays in the number of firms $N$ only very slowly. While under finite variance in the firm size distribution, aggregate volatility decays at rate $\sqrt{N}$ in the number of firms, under Zipf’s Law it decays only at rate $\log N$.

In this paper, we take this statistical result for granted, and relate it to the theoretical framework set up in this paper by first demonstrating how the parameters of the model...
can be calibrated to the observed distribution of firm size – that is, the $\zeta$ that is observed empirically. Then, we use a simplified version of the model to discuss the two key comparative statics regarding the main results of the paper: the role of country size and the role of trade openness in aggregate granular volatility.

In order to proceed, we first consider a simplified version of the model laid out above. In particular, we assume that there is no non-tradeable sector, $N$: $\alpha = \eta_N = \eta_T = 0$. After deriving a number of analytical results under this simplifying assumption, in the next section we present the results of the full quantitative model that features the $N$ sector.

It turns out that the baseline Melitz-Pareto model delivers a power law in firm size. We demonstrate the power law in an autarkic economy, and then discuss how the distribution of firm size is affected by international trade. In our model, the expected sales of a firm as a function of its marginal cost are:

$$x(a) = Da^{1-\varepsilon},$$

where the constant $D$ reflects the size of domestic demand, and we drop the sector and country subscripts. Under the assumption that $1/a \sim \text{Pareto}(b, \theta)$, $\Pr(1/a < y) = 1 - \left(\frac{y}{b}\right)^{\theta}$. Therefore, the power law follows:

$$x \sim \text{Pareto}(b^{\varepsilon-1}D, \frac{\theta}{\varepsilon-1}).$$

Thus, our economy will be granular if $\theta/\varepsilon - 1$ is close enough to 1, which appears to be the case in practice (see Axtell, 2001).

We now derive the expression for aggregate volatility in our economy. Note that there are no aggregate shocks in the model, only the firm-specific idiosyncratic shocks. A firm with marginal cost $a$ and realization of transitory shock $z$ has sales of

$$x^s(a, z) = \frac{X}{P^{1-\varepsilon}} \left(\frac{\varepsilon}{\varepsilon - 1} a z\right)^{1-\varepsilon} = \frac{X}{P^{1-\varepsilon}} \left(\frac{\varepsilon}{\varepsilon - 1} a\right)^{1-\varepsilon} \tilde{z},$$

in sector $s = N, T$, where $\tilde{z} \equiv z^{1-\varepsilon_s}$. We already assumed that $E_z(\tilde{z}) = 1$, and now we further suppose that $\text{Var}_z(\tilde{z}) = \sigma^2$. Expected sales for the firm with productivity $a$ are:

$$E_z[x(a, z)] = \frac{X}{P^{1-\varepsilon}} \left(\frac{\varepsilon}{\varepsilon - 1} a\right)^{1-\varepsilon}.$$  
(13)

The total sales in the economy is defined by:

$$X = \sum_{k=1}^{t} x(a(k), z(k)),$$  
(14)
where $I$ is the total number of operating firms in the tradeable and non-tradeable sectors. Appendix C shows that the variance of the growth rate of aggregate sales, or more precisely of the deviation from the expected aggregate sales, is equal to:

$$\text{Var}_z \left( \frac{\Delta X}{E_z(X)} \right) = \sigma^2 h, \quad (15)$$

where $h$ is the Herfindahl index of production shares of firms in this economy, $h = \sum_{k=1}^{I} h(k)^2$.

This is a familiar expression for the variance of a sum of random variables, and is the same as the one used by Gabaix (2010).

Note that granular volatility only has a chance to be quantitatively relevant if the distribution of firm size is sufficiently fat-tailed. In this case, Gabaix (2010) shows that the conventional Law of Large Numbers fails, and asymptotics are instead governed by a version of Levy’s Theorem, with much slower convergence as the number of firms increases. This implies that idiosyncratic shocks to individual (large) firms average out much more slowly. In the simulation below, we calibrate the exponent of the power law distribution in firm size to available estimates. Equation (15) forms the basis of the quantitative exercise below. We will simulate the world economy with a large number of firms in each country, and calculate how the Herfindahl indices change due to international trade. This will reveal the role of country size, and the contribution of international trade to aggregate (granular) volatility of individual countries as a function of their characteristics.

Gabaix (2010) shows that though aggregate volatility decays in the number of firms much more slowly than under the conventional LLN, nonetheless countries with a greater number of firms $N$ will have lower aggregate volatility. This forms the basis of the relationship between country size and aggregate volatility. As has been understood since Krugman (1980), larger countries – those with higher $L$ – will feature a larger number of firms in equilibrium. Thus, they can be expected to have lower granular volatility. This can be demonstrated most transparently in the autarky equilibrium of a one-sector model. Using equations (4), (5) and (9), assuming a one-sector economy ($\alpha = \eta_N = \eta_T = 0$), and setting the number of countries $C = 1$, the equilibrium number of entrants $\bar{I}$ is proportional to:

$$\bar{I}_{aut} \sim L^{\eta_0 + \frac{1}{\beta} + \frac{1}{\eta_0}}, \quad (16)$$

This is the well-known result that the number of firms increases in country size, measured by $L$. It is immediate that without input-output linkages ($\beta = 1$), the relationship is simply linear.\textsuperscript{13} The presence of input-output linkages actually tends to raise this elasticity above

\textsuperscript{13}In that case, the solution for the equilibrium number of entrants has the particularly simple form:

$$\bar{I}_{aut} = \frac{L}{\eta_0} \frac{\eta_1}{\eta_0}.$$
1: as long as $\beta \varepsilon > 1$, the number of firms responds more than proportionately to the increases in market size. This restriction is likely to be comfortably satisfied in the data, as available estimates put $\beta$ in the range of 0.5, while $\varepsilon$ is typically assumed to be around 6. We discuss the details of how these parameters are calibrated in the quantitative exercise below.\textsuperscript{14} Result (16) thus forms the basis for the first main result of the paper: smaller countries will have fewer firms, and thus higher granular volatility.

How does international trade affect the distribution of firm size and therefore aggregate volatility? As first demonstrated by Melitz (2003), there are two effects, which for our purposes we label the “net entry” effect and the “selection into exporting” effect. When a country opens to trade, the possibility of getting a sufficiently high productivity draw and becoming an exporter induces more potential entrepreneurs to enter and draw their productivity: $\bar{I}$ rises. To demonstrate this effect in the simplest possible way, we assume that countries are symmetric: $L_i = L$, the domestic costs of entry are all the same as well: $f_{ii} = f$. Further, suppose that the trade costs are identical between each country-pair: $\tau_{ij} = \tau \forall i, j$, and $f_{ij} = f^X \forall i, j$, with $\tau_{ii} = 1$ as a normalization. Under trade, the number of entrants is equal to:

\[
\bar{I}_{\text{trade}} = \left[ 1 + (C - 1) \tau^{-\theta} \left( \frac{f}{f^X} \right)^{\frac{\theta - (\varepsilon - 1)}{\varepsilon - 1}} \right]^{\frac{1 - \beta}{\beta}} \frac{1}{\frac{1 - \beta}{\varepsilon - 1} + 1} \bar{I}_{\text{aut}}. \tag{17}
\]

Since the number of entrants under trade is linear in the autarky value, $\bar{I}_{\text{aut}}$, it is clear that the country size effect still operates in the trade equilibrium: larger countries have more firms. Since the additional term in the square brackets is larger than 1, and increasing in the number of countries $C$, opening to trade tends to increase the number of entrants relative to autarky. Since aggregate granular volatility decreases in the number of firms, this “net entry” effect will tend to decrease volatility when a country opens to trade, as long as $\beta \varepsilon > 1$.

The other effect that operates when the country opens to trade is that only the largest firms enter exporting. As a result, the distribution of firm size becomes more unequal under trade: compared to autarky, the least productive firms exit, and only the most productive firms export abroad. Due to competition from foreign varieties, domestic sales and profits decrease. Thus, as a country opens to trade, sales of most firms shrink, while the largest

\textsuperscript{14}One may wonder whether the larger number of number of entrants $I$ actually translates into a larger number of operating firms, since not all firms decide to produce. The number of operating firms is given by $I_{\text{aut}} G(a_A)$, where $a_A$ is the largest marginal cost of the least productive operating firm. The solution to $a_A$ does not depend on $L$ in this model, and thus the number of actual operating firms is linear in $I_{\text{aut}}$. 

14
firms grow larger as a result of exporting. Figure 3 depicts this effect. In the two-country case, there is a single productivity cutoff, above which firms export abroad. Compared to autarky, there is a higher probability of finding larger firms above this cutoff. In the C-country case, with multiple export markets there will be cutoffs for each market, with progressively more productive firms exporting to more and more markets and growing larger and larger relative to domestic GDP. Thus, if the distribution of firm sales follows a power law and the economy is granular, international trade has the potential to increase the size of the largest firms, in effect creating a “hyper-granular” economy, with clear implications for the relationship between trade openness and aggregate volatility. We label this the “selection into exporting” effect. All else equal, this effect implies that after trade opening, granular volatility increases.

While qualitatively both of these results are straightforward applications of the baseline model of trade with heterogeneous firms, the key question is how important this mechanism is quantitatively. In addition, these two mechanisms affect aggregate volatility in the opposite ways. Thus, it is ultimately a quantitative question how reductions in trade costs affect volatility. This is what we turn to in the next section.

Before describing the simulation results, it is important to discuss a number of issues regarding the calibration and quantitative implementation of the model. First, while above we argue that in a one-sector Melitz-Pareto economy, “steady-state” firm size follows a power law with exponent $\theta/(\varepsilon - 1)$, our quantitative model features two sectors, as well as idiosyncratic shocks to firm size. Will the aggregate model economy with these additional features still produce Zipf’s Law in firm size? In order to derive a power law in an aggregate economy with two sectors, we have to compute the (counter-)cdf of the following mixture of distributions: let $Z$ be a random variable that is a power law with exponent $\zeta_1$ with probability $p$, and a power law with exponent $\zeta_2$ with probability $1-p$. It is straightforward to show that the counter-cdf of $Z$ is equal to: $\Pr(Z > z) = pC_1z^{-\zeta_1} + (1 - p)C_2z^{-\zeta_2}$. Importantly, when $\zeta_1 = \zeta_2 = \zeta$, $Z$ is itself is a power law with exponent $\zeta$. This means that a two-sector economy in which both sectors follow a power law with the same exponent will, on aggregate, also exhibit a power law with that exponent. Our quantitative exercise will adopt the assumption that both the $T$ and $N$ sectors follow Zipf’s Law. Though we are not aware of any comprehensive set of estimates of power law exponents in both traded and

15Firm-level studies of dynamic adjustment to trade liberalization appear to find empirical support for these predictions. Pavcnik (2002) provides evidence that trade liberalization led to a shift in resources from the least to the most productive firms in Chile. Bernard et al. (2003) show that a fall in trade costs leads to both exit by the least productive firms and entry by firms into export markets. In addition, existing exporters ship more abroad.
non-traded sectors, di Giovanni et al. (2010) estimate power law exponents for a wide range of both traded and non-traded sectors using a Census of French firms, and find that power law exponents indeed do not differ systematically between traded and non-traded sectors.

Another concern is that even if “steady-state” firm size in the aggregate economy follows Zipf’s Law, when firms are hit by idiosyncratic shocks \( z \), the resulting distribution would be something else. It turns out, however, that power laws are preserved under multiplication by a random variable with finite variance. That is, if firm sales are driven by a combination of a shock that generates Zipf’s Law \( (a \text{ in our notation}) \), and a finite variance shock \( (z) \), the resulting distribution of sales is still \( \text{(Gabaix, 2009, pp. 258-259)} \). Thus, even though we enrich the model with these additional features, the resulting aggregate distribution of firm size that the model produces still follows Zipf’s Law.

Another point regarding calibration of power law parameters is that strictly speaking, when not all firms export selection into exporting implies that the power law exponent estimated on total sales – domestic plus exporting – is lower than \( \theta/(\varepsilon - 1) \). Di Giovanni et al. (2010) explore this bias in detail using the census of French firms, and suggest several corrections to the estimating procedure that can be used to estimate \( \theta/(\varepsilon - 1) \) in an internally consistent way. Their analysis shows that the bias introduced by selection into exporting is not large. Corrected estimates obtained by di Giovanni et al. (2010) show that \( \theta/(\varepsilon - 1) \) is about 1.05, roughly the same as the value used in this paper.

Finally, we discuss the empirical validity of the assumption embedded in equation (15), namely that the volatility of the proportional change in firm sales, \( \sigma \), is invariant to the firm size \( x \). If the volatility of sales decreases sufficiently fast in firm size, larger firms will be so much less volatile that they will not impact aggregate volatility. In fact, an economy in which larger firms are just agglomerations of smaller units each subject to i.i.d. shocks is not granular: shocks to firms cannot generate aggregate fluctuations. Several papers estimated the relationship between firm size and firm volatility of the type \( \sigma = Ax^{-\xi} \) using Compustat data (see, e.g., Sutton, 2002). The benchmark case in which larger firms are simply collections of independent smaller firms would imply a value of \( \xi = 1/2 \), and the absence of granular fluctuations. Instead, the typical estimate of this parameter is about 1/6, implying that larger firms are not that much less volatile than smaller ones. Gabaix (2010) argues that these estimates may not be reliable, since they are obtained using only data on the largest listed firms. In addition, it is not clear whether estimates based on the U.S. reliably reflect the experience of other countries. Hence, our baseline analysis sets \( \xi = 0 \), and a value of \( \sigma \) based on the largest 100 listed firms in the U.S.. In other words, we
assume that all firms in the economy have a volatility as low as largest firms in the economy. However, in the robustness Section 4, we perform our analysis under the assumption that \( \xi = 1/6 \), and show that it makes our results stronger.\(^{16}\)

Another possible determinant of firm volatility that would be relevant to our analysis is exporting. The baseline model assumes that the volatility of firm sales growth does not change when it becomes an exporter. If exporters became systematically more or less volatile than non-exporters, the quantitative results could be affected. We are not aware of any estimates in the literature on whether exporters differ systematically in their sales volatility from non-exporters. We thus used the Compustat Quarterly database of listed U.S. firms together with information on whether a firm is an exporter from the Compustat Segments database. Table A1 estimates the relationship between firm-level volatility – based on either the growth rate of sales or a measure of “granular residual” following Gabaix (2010) – and its export status and size. Controlling for size, the export status is insignificant. Furthermore, the estimated elasticity of volatility with respect to size is similar to what is reported in the literature, and used in the sensitivity check.

3 Quantitative Evidence

Though the analytical results obtained with symmetric countries in a one-sector model are informative, we would like to exploit the rich heterogeneity among the countries in the world. In order to do this, we numerically implement the general multi-country model laid out in Section 2. We use information on country size and trade barriers to solve the model, and then simulate the random draws of firm productivity to compute the Herfindahl indices of firm sales in each country. This will allow us to examine the relationship between granular volatility and various country characteristics in the model, as well as to evaluate the contribution of international trade to aggregate volatility in each country.

In order to fully solve the model numerically, we must find the wages and price indices for each country, \( w_i, P^N_i, P^T_i \), which satisfy equations (8), (9), and (10), jointly with the values of \( \bar{I}^N_i \) and \( \bar{I}^T_i \) that satisfy equations (5). The system is non-reducible, such that all

\(^{16}\)A related point concerns multi-product firms: if large firms sell multiple imperfectly correlated products, then the volatility of the total sales for multiproduct firms will be lower than the volatility of single product firms. Evidence suggests, however, that even in multiproduct firms the bulk of sales and exports is accounted for by a single product line. Sutton (2002) provides evidence that in large corporations, the constituent business units themselves follow a power law, with just a few very large business units and many much smaller ones. Along similar lines, Adalet (2009) shows that in the census of New Zealand firms, only about 6.5% to 9.5% of output variation is explained by the extensive margin (more products per firm), with the rest explained by the intensive margin (greater sales per product).
of the prices and numbers of entrants must be solved simultaneously. To solve this system, we must calibrate all the values of the parameters, as well as country sizes and fixed and variable trade costs.

We simulate the economy under the following parameter values (see Table 1 for a summary). The elasticity of substitution is $\varepsilon = 6$. Anderson and van Wincoop (2004) report available estimates of this elasticity to be in the range of 3 to 10, and we pick a value close to the middle of the range. The key parameter is $\theta$, as it governs the slope of the power law. As described above, in this model firm sales follow a power law with the exponent equal to $\frac{\theta}{\varepsilon - 1}$. In the data, firm sales follow a power law with the exponent close to 1. Axtell (2001) reports the value of 1.06, which we use to find $\theta$ given our preferred value of $\varepsilon$: $\theta = 1.06 \times (\varepsilon - 1) = 5.3$. We set both the elasticity of substitution and the Pareto exponent to be the same in the $N$ and the $T$ sectors. As discussed above, the reduced form exponent in the empirical distribution of firm size, which corresponds to $\theta_s/(\varepsilon_s - 1)$ in sector $s$ is similar between the traded and non-traded sectors. It still could be the case that while $\theta_T/(\varepsilon_T - 1) \approx \theta_N/(\varepsilon_N - 1)$, the actual values of $\theta_s$ and $\varepsilon_s$ differ. Since we do not have reliable information about how these two individual parameters differ across sectors, we adopt the most agnostic and neutral assumption that both $\theta$ and $\varepsilon$ are the same in the two sectors.

We set the value of $\alpha$ – the share of non-tradeables in consumption – to be 0.65. This is the mean value of services value added in total value added in the database compiled by the Groningen Growth and Development Center and extended to additional countries by Yi and Zhang (2010). This type of value is a rather common one, and is also adopted by Alvarez and Lucas (2007). The values of $\beta_N$ and $\beta_T$ – share of labor/value added in total output – are calibrated using the 1997 U.S. Benchmark Input-Output Table. We take the Detailed Make and Use tables, featuring more than 400 distinct sectors, and aggregate them into a 2-sector Direct Requirements Table. This table gives the amount of each input required to produce a unit of final output. Thus, $\beta_s$ is equal to the share of total output that is not used pay for intermediate inputs, i.e., the payments to factors of production. According to the U.S. Input-Output Matrix, $\beta_N = 0.65$ and $\beta_T = 0.35$. Thus, the traded sector is considerably more input-intensive than the non-traded sector. The shares of non-traded and traded inputs in both sectors are also calibrated based on the U.S. I-O Table. According to the data, $\eta_N = 0.77$, while $\eta_T = 0.35$. Thus, more than 75% of the inputs used in the $N$ sector comes from the $N$ sector itself, while 65% of the $T$-sector inputs some from the $T$ sector. Nonetheless, these values still leave substantial room for cross-sectoral
input-output linkages.

Next, we must calibrate the values of \( \tau_{ij} \) for each pair of countries. To do that, we use the gravity estimates from the empirical model of Helpman et al. (2008). That is, combining geographical characteristics such as bilateral distance, common border, common language, whether the two countries are in a currency union and others, with the coefficient estimates reported by Helpman et al. (2008) yields, up to a multiplicative constant, the values of \( \tau_{ij} \) for each country pair. We calibrate the multiplicative constant so as to match the mean and median overall imports/GDP ratios observed in the data in our sample of countries. The advantage of the Helpman et al. (2008) estimates is that they are obtained in an empirical model that accounts explicitly for both fixed and variable costs of exporting, and thus correspond most closely to the theoretical structure in our paper. Note that in this formulation, \( \tau_{ij} = \tau_{ji} \) for all \( i \) and \( j \).\(^{17}\)

Next, we must take a stand on the values of \( f_{ii} \) and \( f_{ij} \). We do not have a good way to calibrate these parameters. In addition, they cannot be calibrated separately from \( b \), the minimum productivity of the firms in the economy. Thus, we proceed by setting \( f_{US,US} \) to a level just high enough to ensure an interior solution for production cutoffs.\(^{18}\) This value of \( f_{US,US} \) is a rather low one, implying that in the U.S. 95% of potential entrepreneurs produce in the U.S.. In order to set \( f_{ii} \) for every other country, we follow di Giovanni and Levchenko (2010a) and use the information on entry costs from the Doing Business Indicators database (The World Bank, 2007a). This database collects information on the administrative costs of setting up a firm – the time it takes, the number of procedures, and the monetary cost – in a large sample of countries in the world. In this application, the particular variable we use is the amount of time required to set up a business. We favor this indicator compared to others that measure entry costs either in dollars or in units of per capita income, because in our model \( f_{ii} \) is a quantity of inputs rather than value. To be precise, if according to the Doing Business Indicators database, in country \( i \) it takes 10 times longer to register a business than in the U.S., then \( f_{ii} = 10 \times f_{US,US} \). Since we do not have data on fixed costs of operating a business that vary by sector, we set \( f_{ii} \) to be equal in the \( N \) and \( T \) sectors.

To measure the fixed costs of international trade, we use the Trading Across Borders module of the Doing Business Indicators. This module provides the costs of exporting a 20-foot dry-cargo container out of each country, as well as the costs of importing the same kind

\(^{17}\)An earlier version of the paper also computed \( \tau_{ij} \) using the estimates of Eaton and Kortum (2002) as a robustness check. The results were very similar.

\(^{18}\)That is, we set \( f_{US,US} \) to a level just high enough that \( a_{ji} < 1/b \) for all \( i, j = 1, \ldots, C \) in all the baseline and counterfactual exercises, with \( 1/b \) being the upper limit of the distribution of \( a(k) \).
of container into each country. Parallel to our approach to setting the domestic cost \( f_{ii} \), the indicators we choose are the amount of time required to carry out these transactions. This ensures that \( f_{ii} \) and \( f_{ij} \) are measured in the same units. We take the bilateral fixed cost \( f_{ij} \) to be the sum of the two: the cost of exporting from country \( j \) plus the cost of importing into country \( i \). The foreign trade costs \( f_{ij} \) are on average about 40\% of the domestic entry costs \( f_{ii} \). This is sensible, as it presumably is more difficult to set up production than to set up a capacity to export.\(^{19}\)

Finally, we set the value of the “exploration cost” \( f_e \) such that the equilibrium number of operating firms in the U.S. is equal to 7 million. According to the 2002 U.S. Economic Census, there were 6,773,632 establishments with a payroll in the United States. There are an additional 17,646,062 business entities that are not employers, but they account for less than 3.5\% of total shipments. Thus, while the U.S. may have many more legal entities than what we assume here, 7 million is a number sufficiently high as to let us consider consequences of granularity. Since we do not have information on the total number of firms in other countries, we choose to set \( f_e \) to be the same in all countries. In the absence of data, this is the most agnostic approach we could take. In addition, since \( f_e \) represents the cost of finding out one’s abilities, we do not expect it to be affected by policies and thus differ across countries. The resulting value of \( f_e \) is 15 times higher than \( f_{US,US} \), and 2.4 times higher than the average \( f_{ii} \) in the rest of the sample. The finding that the ex-ante fixed cost of finding out one’s type is much higher than the ex-post fixed cost of production is a common one in the quantitative models of this type (see, e.g. Ghironi and Melitz, 2005).

Using these parameter values, summarized in Table 1, we can solve the full model for a given vector of \( L_i \). For finding the values of \( L_i \), we follow the approach of Alvarez and Lucas (2007). First, we would like to think of \( L \) not as population per se, but as “equipped labor,” to take explicit account of TFP and capital endowment differences between countries. To obtain the values of \( L \) that are internally consistent in the model, we start with an initial guess for \( L_i \) for all \( i = 1, \ldots, C \), and use it to solve the full model. Given the solution for wages, we update our guess for \( L_i \) for each country in order to match the ratio of total GDPs between each country \( i \) and the U.S.. Using the resulting values of \( L_i \), we solve the model again to obtain the new set of wages, and iterate to convergence (for more on this

\(^{19}\)An earlier version of the paper was more agnostic about the nature of domestic fixed costs \( f_{ii} \), and assumed instead that they are equal (and low) in every country. The results were very similar. In addition, we carried out the analysis setting the bilateral fixed cost to be the sum of domestic costs of starting a business in the source and destination countries: \( f_{ij} = f_{ii} + f_{jj} \). This approach may be preferred if fixed costs of exporting involved more than just shipping, and required, for instance, the exporting firm to create a subsidiary for the distribution in the destination country. The results were virtually identical.
approach, see Alvarez and Lucas, 2007). Thus, our procedure generates vectors $w_i$ and $L_i$ in such a way as to match exactly the relative total GDPS of the countries in the sample. In practice, the results are close to simply equating $L_i$ to the relative GDPS. In this procedure, we must normalize the population of one of the countries. We thus set $L_{US}$ to its actual value of 291 million as of 2003, and compute $L_i$ of every other country relative to this U.S. value. An important consequence of this approach is that countries with higher TFP and capital abundance will have a greater number of potential productivity draws, all else equal, since our procedure will effectively give them a higher $L_i$. This is akin to the assumption adopted by Alvarez and Lucas (2007) and Chaney (2008), that the number of productivity draws is a constant multiple of equipped labor $L_i$. The difference in our approach is that though we take labor-cum-productivity to be a measure of market size, we solve for $\bar{I}_T^i$ and $\bar{I}_N^i$ endogenously within the model.

We carry out the analysis on the sample of the largest 49 countries by total GDP, plus the 50th that represents the rest of the world. These 49 countries together cover 97% of world GDP. We exclude entrepot economies of Hong Kong and Singapore, both of which have total trade well in excess of their GDP, due to significant re-exporting activity. Thus, our model is not intended to fit these countries. (We do place them into the rest-of-the-world category.) The country sample, sorted by total GDP, is reported in Table 2.

3.1 Model Fit: Trade Volumes, Export Participation, and the Size of Large Firms

Before describing the quantitative results, we assess the model fit along three dimensions: overall and bilateral trade volumes; the share of exporting firms in the economy, and the relationship between country size and the size of the largest firms in each country.

Figure 4 reports the scatterplot of bilateral trade ratios $\pi_{ij} = X_{ij}/w_iL_i$. Note that since in the data we only have bilateral trade as a share of GDP, not of total sales, we compute the same object in the model. This captures both the distinction between trade, which is recorded as total value and GDP, which is recorded as value added; as well as the fact that both in the model and in the data there is a large non-traded sector. On the horizontal axis is the natural log of $\pi_{ij}$ that comes from the model, while on the vertical axis is the corresponding value of that bilateral trade flow in the data.20 Hollow dots represent exports from one country to another, $\pi_{ij}, i \neq j$. Solid dots, at the top of the scatterplot, represent sales of domestic firms as a share of domestic absorption, $\pi_{ii}$. For convenience, we add a

---

20Note that the scatterplot is in log-log scale, so that the axes report the trade shares in levels.
45-degree line. It is clear that the trade volumes implied by the model match the actual data well. Most observations are quite close to the 45-degree line. It is especially important that we get the variation in the overall trade openness \((1 - \pi_{ii})\) right, since that will drive the contribution of trade to the granular volatility in each country. Figure 5 plots the actual values of \((1 - \pi_{ii})\) against those implied by the model, along with a 45-degree line. We can see that though the relationship is not perfect, is it quite close.

Table 3 compares the means and medians of \(\pi_{ii}\) and \(\pi_{ij}\)'s for the model and the data, and reports the correlations between the two. The correlation between domestic shares \(\pi_{ii}\) the model and the data for this sample of countries is around 0.48. The correlation between export shares, \(\pi_{ij}\), is actually higher at 0.67.\(^{21}\) Since we use estimated gravity coefficients together with the actual data on bilateral country characteristics to compute trade costs, it is not surprising that out model fits bilateral trade data quite well, given the success of the empirical gravity relationship. Nonetheless, since the gravity estimates we use come from outside of our calibration procedure, it is important to check that our model delivers outcomes similar to observed trade data.

Next, we use the model solution to calculate the percentage of firms that export in the total economy, as well as the tradable sector. In particular, the total number of exporters in a given country \(i\) equals \(I_T^i \times \left( \max_{j \neq i} \left\{a_{ji}^T \right\} \right)^{\theta_T}\). The total number of firms operating in the tradable sector equals \(I_T^i \times \left( \max_j \left\{a_{ji}^T \right\} \right)^{\theta_T}\), and in the non-tradable sector \(I_N^i \times \left( a_{i}^N \right)^{\theta_N}\). We would like to compare the these export participation shares in the model to what is found in the data. Unfortunately, there is no systematic empirical evidence on these shares across countries (and time). However, we have examined publicly available data and existing literature for these shares for 8 countries: U.S., Germany, France, Argentina, Colombia, Ireland, Chile, and New Zealand. Table 4 compares the export participation shares produced by the model to those found in the data in this subset of countries. The first two columns report the values in the model, with the shares of exporters relative to all the firms in the economy in column 1 and in the tradable sector only in column 2. Data sources differ across countries, in particular the shares of exporting firms are sometimes reported only relative to all firms in the economy (which we record in column 3), and sometimes relative to all the firms in the tradeable sector (which we record in column 4).

\(^{21}\)We also experimented with increasing the number of countries in the simulation to 60. The model fit the data well, but there are more zeros in bilateral trade data in the 60-country sample compared to the 50-country one. (With 50 countries, among the 2500 possible unidirectional bilateral trade flows, only 18 are zeros.) Since our model does not generate zero bilateral trade outcomes, we stick with the largest 49 countries in our analysis.
Thus, data in column 3 should be compared to model outcomes in column 1, while data in column 4 should be compared to model outcomes in column 2.

It is clear from this table that the model produces quite reasonable results. Larger countries tend to have fewer exporters relative to the overall number of firms (compare U.S. to Colombia); countries closer to large markets tend to have higher shares of exporters compared to faraway countries (compare Ireland to New Zealand). In no case is the model implied value very far from the data. We should note that by making *ad hoc* adjustments to trade costs in individual countries, we can match each and every one of these numbers exactly. We do not adopt this approach because this information is not available systematically for every country in our sample, and because the available data themselves are noisy. Instead, our approach takes trade costs as implied by a basic gravity model, and the variation in fixed costs as implied by the Doing Business Indicators, which is rather straightforward and does not involve any manual second-guessing. And yet, our model matches the rough values and orders of magnitude more or less right for a number of different countries.

Finally, the model also makes predictions about the features of the firm size distributions across countries that are important for the central mechanism of the paper. We use a large cross-country firm-level database to compare the predictions of the model at the firm level to available data. Though we use the largest available non-proprietary firm-level database in this analysis, coverage is quite uneven across countries and years, implying that measures of concentration may not be reliable or comparable across countries. Nonetheless, as we describe below, the model is quite consistent with the firm-level patterns found in the data.

To compare the model predictions regarding the firm size distribution to the data, we use ORBIS, a large multi-country database published by Bureau van Dijk that contains information on more than 50 million companies worldwide. The data come from a variety of sources, including, but not limited to, registered filings and annual reports. Coverage varies by world region: there are data on some 17 million companies in the U.S. and Canada, 22 million companies in the 46 European countries, 6.2 million companies from Central and South America, 5.3 million from Asia, but only 260,000 from Africa and 45,000 from the Middle East. Importantly, the database includes both publicly traded and privately held firms.

While in principle data are available going back to mid-1990s for some countries, coverage improves dramatically for more recent years. For this reason, we focus our analysis on 2006, the year with the most observations available. The main variable used in the analysis is total sales.
We first assess whether the firm-level indices of concentration in the data behave in the way predicted by the model. To that end, we calculate the Herfindahl indices of firm sales in each country, and regress those on the share of the country in world GDP (the main indicator of country size used throughout the paper), as well as per capita income to control for the level of development. Panel A of Table 5 reports the results – note that all variables are in natural logarithms. The first column uses all 134 countries for which it is possible to calculate the Herfindahl index in ORBIS data. The second column restricts the sample to those countries for which there are at least 100 firms; the third column, at least 1,000 firms. The last column reports the same relationship in the calibrated multi-country model. In the data, the relationship between concentration and country size is highly statistically significant, even controlling for the level of development. At the same time, comparing the slope coefficients in the data to those implied by the model, we can see that the relationship between the concentration and country size is if anything more pronounced in the data than in the model.

The Herfindahl index is the variable most relevant to the quantitative results in the paper. However, because ideally it requires information on the entire firm size distribution, the Herfindahl index may also suffer the most from the incomplete coverage problems in the ORBIS database. Because of this, we also check the model fit using two other indicators of firm size: the combined sales of the largest 10 firms in the country, and the size of the single largest firm. Because these indicators focus on the very largest firms that are measured more reliably in the data, the problems of coverage are less severe.

Panel B of Table 5 compares the relationship between the combined size of the 10 largest firms to country size in the data to the model. There is a significant positive relationship between the absolute size of the largest 10 firms and country size: not surprisingly, larger countries have bigger firms. Thus, qualitatively, the data agree with the model. The magnitudes of the coefficients in the data and the model are quite similar as well, especially in the widest sample of countries. Compared to the coefficients in the more selective samples (columns 2 and 3), the model slightly overpredicts the relative size of large firms in small countries; however, this differential is non-existent if one compares the ninety-five percent confidence intervals of the data and model estimates. Panel C reports the analogous results for the size of the single largest firm in each country. The conclusions are virtually the same as in Panel B.

We conclude that overall, the predictions of the model regarding these aspects of the firm size distribution across countries match fairly well the patterns observed in the data.
3.2 Quantitative Results

Having solved the model given the data on country GDPs and trade costs, we now simulate it using random productivity draws for each firm in each economy. Namely, in each country $i$, in each sector $s$ we draw $\bar{I}_i^s$ productivities from a Pareto($b_s, \theta_s$) distribution. For each firm, we use the cutoffs $a_{ji}^s$ for serving each market $j$ (including its own market $j = i$) given by equation (4) to determine whether the firm operates, and which, if any, foreign markets it serves.

Given the simulations, we next calculate the total sales of each firm as the sum of its sales in each market, and compute the Herfindahl index of firm sales in country $i$. Since the distribution of firm productivities gives rise to a highly skewed distribution of firm sales, there is variation in the Herfindahl index from simulation to simulation, even though we draw as many as 7 million operating firms in a given country. We thus repeat the exercise 1001 times, and take the median values of the Herfindahl index in each country. In parallel, we also compute the Herfindahl index of firm sales in autarky for each country, given all the parameters. This counterfactual exercise allows us to gauge the contribution of international trade to aggregate volatility. Given these values of the Herfindahl index $h$, we can then construct each country’s granular volatility under trade and in autarky using the formula for total variance (15) and a realistic value of $\sigma$. Following Gabaix (2010), we set $\sigma = 0.1$, though since in this paper we will not exploit any variation in $\sigma$ across countries, none of the results will be driven by this choice.

How well does the model predict the actual GDP volatility found in the data? Table 6 presents regressions of actual volatility of GDP growth over the period 1970-2006 against the one predicted by the model ($\sigma_T$) – note that all variables are in natural logarithms. Column (1) includes no controls. We can see that the fit is not perfect ($R^2 = 0.353$), but the relationship is clearly positive and significant. The second column includes GDP per capita. The fit of the model improves, and though the coefficient on the model volatility is somewhat smaller, it remains significant at the 1% level. The next two columns include measures of export structure volatility and sectoral specialization, since our earlier work (di Giovanni and Levchenko, 2009, 2010b) shows that opening to trade can impact aggregate volatility through changes in these variables. Column (3) adds the risk content of exports, which captures the overall riskiness of a country’s export structure. The model volatility remains significant, and the $R^2$ of the regression is now 0.477. Finally, a measure of production

---

22This measure is taken from di Giovanni and Levchenko (2010b). A country’s export structure can be volatile due to a lack of diversification and/or exporting in sectors that are more volatile.
specialization for the manufacturing sector (Herfindahl of production shares) is included in the fourth column.\textsuperscript{23} The number of observations drops to 35 due to limited data availability, but the model volatility still remains significant.

As would be expected, the level of granular volatility is lower than what is observed in the data. Column 1 of Table 7 reports the ratio of the granular volatility implied by the model to the actual GDP volatility found in the data. It ranges between 0.14 and 0.72, with a value of 0.377 for the United States, almost identical to what Gabaix (2010) finds using a very different methodology. Note that the variation in aggregate volatility in the model across countries is generated by differences in country size as well as variation in bilateral trade costs. That gives us a glimpse of how important those two things are to aggregate volatility, when applied through the granular channel.

How much of the elasticity of the aggregate volatility with respect to country size can the model explain? We now plot the predicted volatility as a function of country size in the data and the model. Figure 6 reports the results. Note that since the level of aggregate volatility in the model does not match up with the level in the data, this graph is only informative about the comparison of slopes, not intercepts. In the data the elasticity of GDP volatility with respect to country size is $-0.139 \left(\sigma_{\text{GDP}}\right)$ in this sample of countries. Table A2 reports the results of estimating the volatility-size relationship in the data for various country samples and with and without controls. The baseline coefficient we use in Figure 6 comes from the 50-country sample and controlling for income per capita. Our calibrated model produces an elasticity of $-0.135 \left(\sigma_{T}\right)$, which is extremely close to the one in the data though slightly below it in absolute terms. We can also calculate what this relationship would look like in the absence of trade. Figure 6 reports the volatility-size relationship in autarky. Without trade this relationship is somewhat flatter: the elasticity of volatility with respect to country size in autarky is $-0.115 \left(\sigma_{A}\right)$, lower than the $-0.139$ in the data.

3.2.1 Counterfactuals: The Impact of Trade Openness on Volatility

We now assess the contribution of international trade to the aggregate granular volatility in our sample of countries. Our model yields not only the predicted granular volatility in the simulated trade equilibrium, but also the granular volatility of autarky. Table 7 reports the ratio of the two in each country in the sample. In the table, countries are ranked by

\textsuperscript{23}This measure is calculated using the UNIDO database of sectoral production, and taken from di Giovanni and Levchenko (2009).
overall size, in descending order. We can see that international trade contributes very little to overall GDP volatility in the U.S.. The country is so large and trade volumes are so low that its volatility under trade is only 1.035 times higher than it would be in complete absence of trade. By contrast, smaller countries experience substantially higher volatility as a result of trade openness. For instance, in a country like Romania, the volatility under trade is some 22 percent higher than it would be in autarky.

Having computed what granular volatility would be in the absence of trade, we next carry out the opposite counterfactual experiment: a reduction in trade costs. It would not be very informative to consider totally free trade ($\tau_{ij} = 1 \forall i, j$), since it is unrealistic to model a case in which distance between countries does not affect trade costs, for instance. In this section, we simulate a halving of ad valorem trade costs. When the model was calibrated to the data, the median domestic sales as a share of domestic absorption $\pi_{ii}$ was equal to 0.79, which matches the actual data reasonably well. When trade costs decrease by 50%, $\pi_{ii}$ drops to 0.64, representing a 15 percent increase in world trade as a share of absorption. Given that 65% of consumption is assumed to be non-tradeable, this is a significant increase in the volume of trade.

Column 3 of Table 7 reports, for each country, the ratio of granular volatility under these lower trade costs compared to the baseline. Strikingly, a further reduction in trade costs leads to practically no change in granular volatility on average. For the median country, granular volatility is 0.1% higher under these trade costs relative to today’s trade costs. Evidently, the impact of trade openness on volatility is non-monotonic. How do we explain this result? Changes in trade costs will lead to an expansion in the number of potential entrants ($\bar{I}_s$), which will lower granular volatility. This is the net entry effect. However, the distribution of firm size will also become more fat-tailed, as only the most productive firms expand their sales abroad and become larger. This selection into exporting effect will tend to raise granular volatility, at least for sufficiently high values of $\tau_{ij}$. In the average country, when trade costs are lowered from their current values, the net entry effect dominates the selection into exporting effect, and the volatility decreases slightly.

This explains why smaller countries tend to experience a decrease in volatility in this counterfactual, while larger countries an increase. In the U.S. and Japan, volatility actually goes up slightly, while it falls the most in the small open economies such as Israel and Venezuela. This is because a reduction in trade costs generates a much larger net entry response in smaller countries. Indeed, the percentage change in volatility across countries in this counterfactual exercise has a correlation of 0.62 with the concomitant percentage
change in the total number of entrants $\tilde{I}_N + \tilde{I}_T$. Table A3 present the distribution of changes in aggregate volatility relative to the current level of trade costs for various magnitudes of trade cost reductions, from 10% to 75%. All in all, volatility rises slightly as trade costs are decreased, but the impact always ranges from positive to negative.

4 Robustness Checks and Model Perturbations

4.1 Volatility Varying with Firm Size

An assumption that makes the analysis above possible is that the volatility of the proportional change in sales, $\sigma$, does not change in firm size $x$. As discussed at the end of Section 2, if firm-level volatility decreases sharply enough in size, shocks to large firms will not generate aggregate volatility. In practice, however, the negative relationship between firm size and volatility of its sales is not very strong. Stanley et al. (1996) and Sutton (2002) estimate the relationship of the type $\sigma = Ax^{-\xi}$, and find a value of $\xi = 1/6$. That is, firm-level volatility does decrease with size, but this elasticity is quite low. To check robustness of our results, we allow the firm-specific volatility to decrease in firm size as estimated by these authors. In that case, aggregate (granular) variance is given by

$$\text{Var}_z \left( \frac{\Delta X}{E_z(X)} \right) = \sum_{k=1}^{I} \left( Ax(k)^{-\xi} h(k) \right)^2,$$

where, once again, $x(k)$ are sales of firm $k$, while $h(k)$ is the share of firm $k$’s sales in total output in the economy.

The rest of the simulation remains unchanged. Since we are not matching the level of aggregate volatility, just the contribution of trade, we do not need to posit a value of the constant $A$. However, it would be easy to calibrate to match the volatility of the top 100 firms in the U.S. as reported by Gabaix (2010), for example. Note that compared to the baseline simulation, modeling a decreasing relationship between country size and volatility is a double-edged sword: while larger firms may be less volatile as a result, smaller firms are actually more volatile. This implies that the impact of either country size or international trade will not necessarily be more muted when we make this modification to the basic model.

Table 8 reports the results of this robustness check. For ease of comparison, in row 1 of this table, we report the two key results from the baseline analysis. The first key result is that the model generates higher volatility in smaller countries, with the elasticity of volatility with respect to country size of $-0.135$. (As we report above, in the data this
elasticity is very close, $-0.139.$) The second column reports the second key result of the paper, which is the contribution of trade openness to aggregate volatility. That is, in column 2 we report the mean ratio of aggregate volatility under the current level of trade openness relative to complete autarky.

In row 2 of Table 8 we report these two main results of the paper under the alternative assumption that firm volatility decreases with firm size. In this case, smaller countries are even more volatile relative to large ones (the size-volatility elasticity doubles to $-0.286$), and the contribution of trade is also larger, with trade leading to an average 29% increase in volatility, compared to 9.7% in the baseline. Somewhat surprisingly, therefore, allowing volatility to decrease in firm size implies a larger contribution of trade to aggregate volatility, not a smaller one. In fact, this is the case in every country in the sample save the U.S..

4.2 Robustness to Parameter Changes

We assess the sensitivity of the results in two additional ways. The first is an alternative assumption on the curvature of the firm size distribution. Eaton et al. (2008) estimate a range of values for $\theta/(\varepsilon - 1)$ of between 1.5 and 2.5. Though Gabaix (2010) shows that the shocks to large firms can still generate granular volatility when the power law exponent is less than 2, it is still important to check whether the main results of our paper survive under alternative values of $\theta/(\varepsilon - 1)$. Row 3 of Table 8 presents the two main results of the paper under the assumption that the slope of the power law in firm size is 1.5 instead of 1.06. Though in each case the numbers are slightly smaller in absolute value, the main qualitative and quantitative results remain unchanged: smaller countries still have lower volatility, with elasticity of $-0.123$, and trade contributes slightly more to granular volatility, with the average increase of 11.6%.

Second, we re-calibrate the model under two alternative values of $\varepsilon$, 4 and 8. In these exercises, we continue to assume that the economy is characterized by Zipf's Law, so that $\theta/(\varepsilon - 1)$ is still equal to our baseline value of 1.06. Thus, as we change $\varepsilon$, we change $\theta$ along with it. The results are presented in the last two rows of Table 8. The size-volatility relationship is robust to these alternative assumptions. The elasticity of volatility with respect to country size is similar to the baseline, though slightly lower when $\varepsilon = 4$. The contribution of trade is quite similar as well, with 9.9% and 11.1% for $\varepsilon = 4$ and $\varepsilon = 8$, respectively.
5 Conclusion

Recent literature in both macroeconomics and international trade has focused attention on the role of firms. Recent research argues that large firms matter for the macroeconomy. Gabaix (2010) demonstrates that if the distribution of firm size follows a power law with an exponent close to $-1$ – which appears to be the case in the data – shocks to the largest firms can lead to aggregate fluctuations, which are dubbed “granular.” We now know that international trade is mostly carried out by the largest firms (Bernard et al., 2007), and these firms are relatively more important in the overall economy because of their exporting activity (Melitz, 2003).

This paper argues that the preponderance of large firms and their role in aggregate volatility can explain two empirical regularities found in cross-country data: (i) smaller countries are more volatile, and (ii) more open countries are more volatile. We calibrate and simulate a multi-country model of firm-level production and trade that can generate granular fluctuations. The model matches quite well a number of features of the data, such as observed bilateral and overall trade volumes, export participation ratios, and the size of the largest firms in different countries. We show that the model reproduces very well the elasticity of GDP volatility with respect to country size found in the data. The counterfactual exercises reveal that the contribution of international trade to aggregate volatility varies a great deal depending on country characteristics. While it is minimal in large, relatively closed economies like the U.S. or Japan, trade increases volatility by as much as 20% in small open economies such as Denmark or Romania. However, we also find that the impact of trade on volatility is non-monotonic: our model implies that reductions in trade costs relative to their present levels will if anything reduce aggregate volatility slightly in most countries.

Recent research incorporates heterogeneous firms into fully dynamic general equilibrium macroeconomics models, focusing on the impact of persistent aggregate shocks and firm entry and exit (Ghironi and Melitz, 2005; Alessandria and Choi, 2007). The importance of firm-specific idiosyncratic shocks for macroeconomic volatility via the granular channel emphasized in this paper should be viewed as complementary to this work. Future research incorporating these different mechanisms, as well as bringing disaggregated data to the models, will help provide an even more complete picture of the macroeconomic impact of trade integration.
Appendix A  Impact of Country Size and Openness in a Canonical IRBC Model

This Appendix evaluates whether the standard International Real Business Cycle (IRBC) model produces the relationship between country size and volatility observed in the data, and whether it features a positive relationship between openness and growth. To answer these questions, we implement the standard IRBC model and vary relative country size and openness, focusing on the response of aggregate volatility to those two variables. The modeling approach and calibration details follow as closely as possible the classic treatment of Backus et al. (1995, henceforth BKK).

A.1 Country Size

Let there be two economies, Home and Foreign, with Foreign variables denoted by an asterisk. In the home country, each agent’s period utility depends on consumption and leisure:

\[ u(c_t, n_t) = \frac{c^\mu (1 - n_t)^{1-\mu}^{1-\eta} - 1}{1 - \eta}, \]

where \( c \) is an individual’s consumption, and \( n \) is the share of the time endowment dedicated to working. In order to model countries of differing sizes, we follow the approach of Head (1995) and Crucini (1997) and assume that the Home country is populated by \( T \) identical agents, and Foreign is populated by \( T^* \). Adding up utilities of all agents in Home, we obtain how total welfare depends on the aggregate consumption \( C_t \) and total labor supply \( N_t \):

\[ U(C_t, N_t) = T u(c_t, n_t) = T \left( \frac{[c^\mu (1 - n_t)^{1-\mu}^{1-\eta} - 1]}{1 - \eta} \right) \]

\[ = T \left\{ \frac{[(C_t^\mu (T - N_t))^{1-\mu}^{1-\eta} - 1]}{1 - \eta} \right\} \]

\[ = T^n\left( C_t^\mu (T - N_t)^{1-\mu}^{1-\eta} - T \right) \]

with the analogous aggregation in Foreign.

Production uses both labor and capital. Total output in Home is given by the Cobb-Douglas production function: \( Y_t = Z_t K_{t-1}^{\rho} N_t^{1-\rho} \), where \( Z_t \) is aggregate productivity, and \( K_{t-1} \) is the capital stock available for production at the beginning of period \( t \). Capital accumulation is subject to standard quadratic adjustment costs: investment of \( I_t \) in period \( t \) has the adjustment cost equal to \( \frac{\phi}{2} \left( \frac{(I_t - \delta K_{t-1})^2}{K_{t-1}} \right) \), where \( \delta \) is the depreciation rate. That
is, it is costless to invest to cover depreciation exactly, but deviations from that incur an additional cost.

Finally, (log) productivity follows a bivariate AR(1) process:

\[
\begin{bmatrix}
\log Z_t \\
\log Z^*_t
\end{bmatrix} = \begin{bmatrix}
(1 - \psi) \log Z_{t-1} + \psi_{11} \psi_{12} & \psi_{21} \psi_{22}
\end{bmatrix} \times \begin{bmatrix}
\log Z_{t-1} \\
\log Z^*_{t-1}
\end{bmatrix} + \begin{bmatrix}
\epsilon_t
\end{bmatrix}
\]

Following BKK, Head (1995), and Crucini (1997), we assume that there is a single good, produced in both countries, that is used for both consumption and investment. Markets are complete, and thus equilibrium is found by solving a global planning problem that maximizes the net present value of world welfare subject to the global resource constraint:

\[
C_t + C^*_t + K_t - (1 - \delta)K_{t-1} + \frac{\phi (K_t - K_{t-1})^2}{K_{t-1}} + K^*_t - (1 - \delta)K^*_{t-1} + \frac{\phi (K^*_t - K^*_{t-1})^2}{K^*_{t-1}} \\
\leq Z_t K^\rho_{t-1} N^{1-\rho}_t + Z^*_t K^\rho^\rho_{t-1} N^{1-\rho}_t
\]

that is, global output \(Z_t K^\rho_{t-1} N^{1-\rho}_t + Z^*_t K^\rho^\rho_{t-1} N^{1-\rho}_t\) is used for consumption in the two countries, and investment inclusive of adjustment costs.

With the exception of the differing country sizes, the model is standard, and is solved using conventional techniques of a first-order approximation around a deterministic steady state. In choosing parameter values, we follow BKK: the discount rate is set to 0.99; risk aversion/intertemporal elasticity of substitution \(\eta = 2\); the weight of consumption in utility \(\mu = 0.5\), depreciation rate \(\delta = 0.025\), capital share \(\rho = 0.36\), the persistence of the technology shock \(\psi_{11} = \psi_{22} = 0.906\), the spillover terms \(\psi_{12} = \psi_{21} = 0.088\) and the adjustment cost of investment parameter \(\phi = 8.5\). With identical country sizes, the model is exactly the same as in BKK, and we do not discuss its properties here.

We simulate the model for a range of relative country sizes intended to mimic the size of countries relative to the rest of the world found in our data: from two countries accounting for 0.5 of the world GDP at one extreme to one country accounting for 2.5% of world GDP and the other for 97.5% of world GDP (in our data, the smallest countries are about 2% of world GDP). For each pair of relative country sizes, we draw random shocks \(\epsilon_t\) and \(\epsilon^*_t\) for 80,100 periods, and calculate the volatility of GDP growth for the last 80,000 periods (discarding the first 100 “burn-in” periods). Using these model-generated volatilities, we run the same regression as we do with the actual data, regressing log standard deviation of GDP growth on log share of the country in the world GDP. Consistent with previous findings (Head, 1995; Crucini, 1997), we do find that smaller countries are more volatile, but the elasticity of volatility with respect to country size is –0.004, two orders of magnitude
lower than the volatility found in the data (−0.139), or the granular model in this paper
(−0.135). We conclude that the standard IRBC model is not as successful as our model at
generating the size-volatility relationship observed in the data.

A.2 Trade Openness

Because the one-good model above has steady state imports/GDP equal to zero, in order
to evaluate the relationship between observed openness (trade/GDP) and volatility in the
standard IRBC model, we augment it to feature Armington aggregation between domestic
and foreign goods. That is, Home consumption and investment inclusive of adjustment
costs comes from CES aggregation of domestic and foreign intermediate inputs:

\[ C_t + K_t - (1 - \delta)K_{t-1} + \frac{\phi (K_t - K_{t-1})^2}{2 K_{t-1}} = \left[ \omega \left( y_{ht}^h \right)^{\frac{\varepsilon+1}{\varepsilon}} + (1 - \omega) \left( y_{ft}^f \right)^{\frac{\varepsilon+1}{\varepsilon}} \right]^{\frac{\varepsilon}{\varepsilon-1}}, \quad (A.1) \]

where \( y_{ht}^h \) is the output of the Home intermediate good that is used in Home production, and
\( y_{ft}^f \) is the amount of the Foreign intermediate used in Home production. In this standard
formulation, consumption and investment are perfect substitutes, and Home and Foreign
goods are aggregated in a CES production function. Domestic output is then divided
between domestic intermediate inputs \( y_{dt}^d \) and exports \( y_{ht}^h \):

\[ Y_t = y_{dt}^d + y_{ft}^f = Z_t K_t^\rho N_{t}^{1-\rho} \]

The rest of the model and calibration details remain unchanged. The key parameter is the
Armington elasticity of substitution between domestic and foreign goods \( \varepsilon \). We perform our
simulation for two standard values of this elasticity, the “classic” BKK value of 1.5, and the
alternative value suggested by BKK, and used in the subsequent literature of 0.9, implying
that domestic and foreign goods are complements. Once again, we do not discuss the details
of the model’s performance, as it is highly standard. Instead, we simulate the model for a
range of values of trade openness. Following BKK, we use the parameter \( \omega \) – home bias in
preferences – to vary trade openness. As it happens, the steady state ratio of imports to
GDP corresponds exactly to \( \omega \). Thus, we solve the model for a range of values of \( \omega \) between
0.01 to 0.5, the latter being the case of no home bias. Similarly to the previous exercise, we
then simulate the model for 80,100 periods, recording the volatility of the growth rate of
output for each level of trade openness. It turns out that the sign of the openness-volatility
relationship depends crucially on the Armington elasticity \( \varepsilon \). For \( \varepsilon = 1.5 \), output volatility
actually decreases in openness, with the elasticity of standard deviation of output growth
with respect to imports/GDP of −0.029. However, under \( \varepsilon = 0.9 \), volatility increases in
openness, with an elasticity of similar order of magnitude but reverse sign, 0.085. Thus, it appears that there is no “natural” openness-volatility relationship in the standard IRBC framework; instead, the direction of the relationship depends a great deal on key parameter values.

Appendix B  Endogenous Markups

The model in the main text is solved under the assumption that each firm treats the sectoral price level as given setting its prices and maximizing profits. This assumption is adopted in the overwhelming majority of the trade under monopolistic competition literature that followed Krugman (1980) and Melitz (2003). However, because our paper emphasizes the role of extremely large firms in the economy, it is important to assess whether, and to what extent, price setting by the large firms departs from the constant-markup benchmark. Unfortunately, fully taking this phenomenon into account would be impractical. To incorporate this feature into the solution of the model would lead us to lose all of the analytical results that help solve the model, such as the expressions for the price levels and sales. This is because each firm’s profit-maximizing price is a function of all the other firms’ prices, so that just to pin down a single firm’s price, quantity, total sales, and profits, we would have to solve a fixed point problem involving all the firms selling to that market. In the trade equilibrium, to do this while at the same time solving for wages and imposing a free entry condition that pins down the equilibrium number of firms would not be feasible.

However, in some simpler cases we can check whether this phenomenon is quantitatively important. In this appendix, we solve for the individual firms’ prices and the aggregate price level in the autarky equilibrium for any particular draw of productivities. We start by finding the profit-maximizing price for each firm taking the prices of all the other firms as given. We then take all the firms’ prices, and use that as the next starting point for finding each firm’s profit maximizing price. Iterating to convergence, we obtain the full set of equilibrium prices for each firm, as well as the overall price levels in this economy. We then compare those to the individual firm prices and sectoral price levels that we would get if we instead assumed the constant markup equal to $\varepsilon / (\varepsilon - 1)$.

Solving the firm’s profit maximization problem, firm $k$’s optimal price $p(k)$ is given implicitly by the following expression:

$$
p(k) = \frac{\varepsilon}{\varepsilon - 1} \cdot \text{ca}(k) \times \frac{1}{1 - \sum_{l=1}^{n} \frac{p(l)^{1-\varepsilon}}{p(k)}}
$$

(B.1)
where $c$ is the cost of the input bundle, $a(k)$ is the firm’s marginal cost and there are $J$ firms in this market in total. The first term is the simple “constant-markup” price that is used in the large majority of the literature. The second term is the adjustment due to the firm’s effect on the overall price level.

This equation does not have an analytical solution in $p(k)$, making it necessary to resort to numerical simulations. We thus take each country’s autarky equilibrium number of firms, draw productivity for each firm, and solve for a fixed point in prices when each firm sets its price according to equation (B.1). Note that while this does not represent the full solution to the autarky model, it does allow us to evaluate how much flexible-markup prices differ from the constant-markup prices for the constant-markup equilibrium number of firms.

It turns out that in our sample of 50 countries, the maximum proportional difference between the flexible-markup price and the simplistic constant-markup price is 0.0225 (not percentage points of markup!). This is the maximum over all the firms in all the countries and all the sectors $s = N, T$. Thus, it appears that even for the very largest firms in the smallest countries, the constant-markup case is a very good approximation of their pricing behavior.

When it comes to the aggregate price levels, this phenomenon is even less important. Among the 50 countries and the 2 sectors ($N$ and $T$) in our model, the maximum proportional difference in the price level is 0.4% (0.004). Thus, the general equilibrium effect whereby a large firm will take into account the impact of its own price on the aggregate price level appears to be quite minor quantitatively.

What is the intuition for this result? Though the flexible-markup price (B.1) does not have an analytical solution, it can be approximated as follows. The term $p(k)^{1-\varepsilon} / \sum_{l=1}^{J} p(l)^{1-\varepsilon}$ roughly corresponds to the share of the firm in total sales in the market. The term $ca(k)/p(k)$ is the inverse of the markup over the marginal cost, which we will approximate by $(\varepsilon - 1)/\varepsilon$. The price then becomes, approximately:

$$p(k) \approx \frac{\varepsilon}{\varepsilon - 1} ca(k) \times \frac{\varepsilon}{\varepsilon - \text{share}(k)}$$

where $\text{share}(k)$ is the share of firm $k$ in total sales in the market. That second term is thus the proportional deviation of the actual profit-maximizing price from the simplistic constant-markup price. How large does the firm have to be before this adjustment starts to appreciably affect the price? Under the baseline value of $\varepsilon = 6$, when $\text{share}(k)$ is 5%, the $\varepsilon/(\varepsilon - \text{share}(k))$ adjustment amounts to 1.0084; when $\text{share}(k)$ is 10%, that adjustment
is 1.0169, and when \( \text{share}(k) \) is 50%, the adjustment is 1.0909. Thus, even for firms that capture 50% of the total sales in a market, we are no more than 10% off if we simply assume the constant-markup price. As described above, given the number of firms that we actually draw for each country, we are never more than 0.0225 off for any given firm in the world.

This derivation can be used to make an additional point. While we perform this simulation for the autarky case, under trade these price deviations will become strictly smaller. This is because after trade opening, the market share of each firm in any given market will be strictly lower than in autarky, due to the appearance of foreign varieties (this result is well known in the heterogeneous firms literature). This in turn implies that the markup adjustment term \( \varepsilon/(\varepsilon - \text{share}(k)) \) will shrink further under trade.

**Appendix C Aggregate Volatility Derivation**

Given the expression for the actual sales of the firm with a transitory shock \( z \) in (12), and the expected sales of the firm with productivity \( a \) in (13), the actual sales as an approximation around \( E_z [x(a, z)] \) are:

\[
x(a, z) = E_z [x(a, z)] + \left. \frac{dx}{d\tilde{z}} \right|_{\tilde{z}=1} \Delta \tilde{z}
\]

Therefore, the proportional change in \( x(a, z) \), or the growth rate, is given by:

\[
\frac{\Delta x(a, z)}{E_z (x(a, z))} = \tilde{z} - 1,
\]

and the variance of this growth rate is:

\[
\text{Var}_z \left( \frac{\Delta x(a, z)}{E_z (x(a, z))} \right) = \sigma^2.
\]

The total sales in the economy are given by (14), thus the change in the total sales relative to the non-stochastic steady state (the growth rate) is:

\[
\frac{\Delta X}{E_z X} = \sum_{k=1}^{I} \frac{\Delta x(a(k), z(k))}{E_z X} = \sum_{k=1}^{I} \frac{\Delta x(a(k), z(k))}{E_z [x(a(k), z(k))] E_z X}.
\]
This means that the aggregate volatility is

\[
\text{Var}_{z} \left( \frac{\Delta X}{E_{z}X} \right) = \text{Var}_{z} \left( \sum_{k=1}^{l} \frac{\Delta x(a(k), z(k))}{E_{z}[x(a(k), z(k))] \frac{E_{z}[x(a(k), z(k))]}{E_{z}X}} \right)
\]

\[
= \sum_{k=1}^{l} \text{Var}_{z} \left( \frac{\Delta x(a(k), z(k))}{E_{z}[x(a(k), z(k))] \frac{E_{z}[x(a(k), z(k))]}{E_{z}X}} \right)^2
\]

\[
= \sigma^2 \sum_{k=1}^{l} \left( \frac{E_{z}[x(a(k), z(k))]}{E_{z}X} \right)^2
\]

\[
= \sigma^2 \sum_{k=1}^{l} h(k)^2,
\]

where \(h(k)\) is the share of the firm \(k\)'s sales in total sales. As expected, the volatility of total output in the economy is equal to the volatility of an individual firm's output times the Herfindahl index of production shares.

Appendix D  Data Description and Sources

Data on total GDP come from the World Bank’s World Development Indicators database (The World Bank, 2007b). In order to compute the share of each country in world GDP, we compute shares of each country in world GDP expressed in nominal U.S. dollars in each year over the period 1970-2006, and take the average share over this period. To compute the GDP volatility, we compute the yearly growth rates of GDP expressed in constant local currency units, and take the standard deviation of that growth rate over 1970-2006. We also use the real PPP-adjusted per capita GDP figures from The World Bank (2007b) to control for the overall level of development in Section 3.

To obtain values \(\tau_{ij}\) following the estimates of Helpman et al. (2008), we use data on bilateral distance, common border, whether the country is an island or landlocked, common language, and colonial ties from Centre d’Etudes Prospectives et Informations Internationales (CEPII). Data on legal origins come from La Porta et al. (1998). Finally, information on currency unions and free-trade areas come from Rose (2004), and supplemented by internet searches whenever needed.

Notes: This table compares, for selected countries, the share of exporters among all firms in the model (column 1) and the share of exporters among the tradeable sector firms in the model (column 2) with available estimates of corresponding shares in existing literature. Since for some countries, data are reported relative to all the firms in the economy, while for other countries it is reported relative to all the firms in the traded sector, column 3 (data) should be compared to column 1 (model), and column 4 (data) should be compared to Column 2 (model). For the United States, data are imputed based on publicly available U.S. Economic Census data on the numbers of firms by sector, together with the summary statistics for the numbers of exporters reported in Bernard et al. (2007). Data for France is based on authors’ calculations using the French Census data in di Giovanni et al. (2010). Data for Germany are from Arndt et al. (2009) (Table A2). Data for Argentina come from Bustos (2010), Table D.1. For New Zealand, data come from Fabling and Sanderson (2008), Table 4. Data on Ireland come from Fitzgerald and Haller (2010), Table 1. Data for Chile come from private communication with Miguel Fuentes at the Central Bank of Chile. Data for Colombia come from authors’ calculations based on the 1991 Colombian census of manufactures that has been used in numerous papers starting with Roberts and Tybout (1997). Note that this value is much lower than what is implied by the model partly because it is for 1991. The share of exporters in Colombia is likely to have risen substantially between 1990 and today.

Notes: Robust standard errors in parentheses; + significant at 10%; * significant at 5%; ** significant at 1%. All variables are in natural logarithms. The dependent variables are based on 2006 firm sales data from ORBIS, where we have dropped energy, commodity, and public service firms. Column labeled ‘All’ uses all available countries; columns ‘obs(S)≥100’/‘obs(S)≥1000’ constrain the sample to countries with at least 100/1000 firm-sales observations. ‘Size’ is a country’s GDP relative to world GDP; ‘GDP per capita’ is PPP-adjusted per capita income. Column ‘Model’ reports the corresponding relationship in the calibrated model used in the paper.

Notes: ‘Trade/Actual’ reports the ratio of granular volatility implied by the model under trade to the actual volatility of GDP growth. In calculating the granular volatility, this column assumes that the firm-level volatility is equal to $\sigma = 0.1$. ‘Trade/Autarky’ reports the ratio of granular volatility under trade to the granular volatility under autarky for each country. ‘Further Trade Opening’ reports the ratio of granular volatility under a 50% reduction in iceberg trade costs $\tau_{ij}$ to the granular volatility as implied by the model under current trade costs.

Notes: This table reports the contribution of international trade to aggregate volatility (ratio of volatility under trade to the volatility in autarky) under alternative assumptions. Row (1) reports the results of a simulation in which the firm-specific volatility decreases in firm size. Row (2) reports the results of applying a power law coefficient of 1.5 rather than the baseline of 1.06. Rows (3) and (4) report the results when using an elasticity of substitution of 4 or 8, respectively.

Notes: Robust standard errors in parentheses; + significant at 10%; * significant at 5%; ** significant at 1%. This table presents the results from regressing a measure of firm-level sales volatility on measures of its export status (‘Exporter’) and size (‘Sales’). Columns (1) and (2) of ‘Growth’ take the natural logarithm of the standard deviation of firm real sales as the dependent variable. Columns of (1) and (2) uses a granular volatility measure, which is calculated as the standard deviation of the estimated residuals, $\hat{\varepsilon}_{ist}$, from the following firm-level panel regression: $\Delta \log (Sales_{ist}) = \alpha_i + \alpha_{st} + \varepsilon_{ist}$, where $i$ is a firm, $s$ is a sector, and $t$ is a quarter, so that $\alpha_i$ is a firm-level effect, and $\alpha_{st}$ is a sector×time effect. Standard deviations are calculated over the given sample period, while export status and measures of firm size are averaged over the period. Regressions include sector-level fixed effects at the 4-digit SIC. ‘All’ includes all firms, while ‘Restricted’ excludes firms in the commodity, energy, and public sectors. Data are taken from Compustat’s quarterly database.

</table>

Notes: Robust standard errors in parentheses; + significant at 10%; * significant at 5%; ** significant at 1%. All variables are in natural logarithms. The dependent variable is the log of the standard deviation of per capita GDP growth over the period 1970-2006. Size is a country’s GDP relative to world GDP; GDP per capita is PPP-adjusted per capita income. All right-hand side variables are averages over 1970-2006.

Notes: This table reports percentiles and minimum and maximums of the ratio of granular volatility under a four reductions in iceberg trade costs $\tau_{ij}$ to the granular volatility as implied by the model under current trade costs.
Figure 1. Korean Business Groups Sales As a Share of GDP and Total Exports

Notes: This table reports the sales of the top 10 Korean business groups, as a share of Korean GDP (blue/dark bars) and total Korean exports (red/light bars). Source: Korean Development Institute.
**Figure 2.** The Timing of the Economy

Each entrant $k = 1, \ldots, I$ finds out its type $a$, and decides whether or not to produce and export. Those that decide to enter/export pay the fixed costs of producing/exporting. Existing producers learn the transitory shock $z$.

Produce with marginal cost $az$; consume; markets clear.

**Figure 3.** The Analytical Power Law in the Melitz-Pareto Model

Notes: This figure depicts the distribution of firm size, measured by sales, and how it changes as it moves from Autarky to a 2-Country Trade equilibrium, and finally to a $C$-Country Trade equilibrium. In the two-country case, there is a single productivity cutoff, above which firms export abroad. Compared to autarky, there is a higher probability of finding larger firms above this cutoff. In the $C$-country case, with multiple export markets there will be cutoffs for each market, with progressively more productive firms exporting to more and more markets and growing larger and larger relative to domestic GDP.
Figure 4. Bilateral Trade Shares: Data and Model Predictions

Notes: This figure reports the scatterplot of domestic output ($\pi_{ii}$) and bilateral trade ($\pi_{ij}$), both as a share of domestic absorption. The values implied by the model are on the horizontal axis. Actual values are on the vertical axis. Solid dots represent observations of $\pi_{ii}$, while hollow dots represent bilateral trade observations ($\pi_{ij}$). The line through the data is the 45-degree line.
Figure 5. Trade Openness: Data and Model Predictions

Notes: This figure reports total imports as a share of domestic absorption \((1 - \pi_{ii})\). The values implied by the model are on the horizontal axis. Actual values are on the vertical axis. The line through the data is the 45-degree line.
Figure 6. Volatility and Country Size: Data and Non-Symmetric Model Predictions

Notes: This figure plots the relationship between country size and aggregate volatility implied by the data (conditioning for per-capita GDP), the model with non-symmetric countries under trade, and the model with non-symmetric countries in autarky. The dots represent actual observations of volatility. Note that the data points and regression line are shifted by a constant for ease of visual comparability with the model regressions lines. Source: The World Bank (2007b).
